

Impact of Survivorship Care on Young Adult Survivors of Childhood Cancer With Post-Traumatic Stress Symptoms

Wilhelmenia L. Ross, MPH, Hannah-Rose Mitchell, MPH, Neel S. Iyer, DO, MPH, Sheila Judge Santacroce, PhD, RN, CPNP, FAANP, and Nina S. Kadan-Lottick, MD, MSPH

OBJECTIVES: To assess post-traumatic stress symptoms (PTSSs) in young adult survivors of childhood cancer not receiving survivorship care and to determine whether attending a survivorship-focused healthcare visit was associated with changes in PTSSs.

SAMPLE & SETTING: 44 young adult survivors from the Yale Cancer Center in Connecticut without prior survivorship clinic attendance.

METHODS & VARIABLES: As part of a larger trial, participants were randomized to a model of survivorship-focused health care. The University of California at Los Angeles Post-Traumatic Stress Disorder (PTSD) Reaction Index assessed PTSS severity and frequency before and after the visit.

RESULTS: At baseline, almost half of the participants were classified as partial PTSD likely or PTSD likely. Many met criteria for elevated levels of individual symptoms, particularly avoidance or numbing. At follow-up, PTSSs did not differ significantly from baseline.

IMPLICATIONS FOR NURSING: Survivorship care should be encouraged by nurses in healthcare settings that do not specialize in caring for long-term survivors. Nurses should facilitate screening for PTSSs and promote interventions among survivors completing cancer therapy to help them transition to survivorship care.

Survivors of childhood cancer may be psychologically affected by the cancer experience throughout life (Brinkman, Recklitis, Michel, Grootenhuis, & Klosky, 2018). Potential outcomes they are at risk for include post-traumatic stress symptoms (PTSSs), such as avoidance or numbing (e.g., avoiding event-related stimuli), hyperarousal (e.g., hypervigilance), and re-experiencing (e.g., intrusive memories) (American Psychiatric Association [APA], 2013). Even a patient who does not meet diagnostic criteria for full-blown post-traumatic stress disorder (PTSD) can exhibit PTSSs, which can impair daily functioning. Although PTSSs have been identified in childhood cancer survivors (Koutná, Jelínek, Blatný, & Kepák, 2017; Stuber et al., 2010), PTSSs have not been examined specifically in young adult survivors who have not received survivorship care since completing treatment. PTSSs may stem from the diagnosis of a life-threatening illness, which is recognized as a potentially traumatic event (APA, 2013), and ongoing exposures to other potential traumas (e.g., surgeries, hospitalizations, deaths of other children) inherent in the cancer experience (Allen et al., 2018; Stuber, Kazak, Meeske, & Barakat, 1998). The emergence of such symptoms aligns with a pediatric medical traumatic stress model, which proposes that the experience of medical illness can cause physiologic or psychological effects (Price, Kassam-Adams, Alderfer, Christofferson, & Kazak, 2016).

Background

PTSSs are associated with other psychological outcomes (e.g., depression), impaired social functioning, poor quality of life, and long-term physical health decline (Ahmadi et al., 2018; Boscarino, 2004; Kroenke, Spitzer, Williams, Monahan, & Löwe, 2007; Meeske, Ruccione, Globe, & Stuber, 2001). Among individuals with medical-related trauma (e.g., intensive care stay),
